

The assumption: gas is transparent
(thin-target formula)

every neutron samples the whole 60 mm column:
 $P(\text{rare}) = (\text{atoms}/\text{cm}^2) \times \sigma_{n\gamma}$
grows with thickness

The reality below 1 keV: gas is opaque
(mean free path ≈ 0.15 mm at 25 meV)

absorbed within a fraction of a mm of entering
(red band exaggerated); $P(\text{rare}) \rightarrow \sigma_{n\gamma}/\sigma_{np} = 1.0 \times 10^{-8}$
thickness-independent
